# Markov chain Monte Carlo (MCMC)

(Literature: Givens and Hoeting, 7.1, 7.3; Gentle, 7.3-7.4)

- The algorithms considered so far generate sequences of **independent** observations which follow the target distribution exactly
- We will now consider a method which generates a sequence of **dependent** observations which follow the target distribution **approximately**
- The next observation ( $t + 1$ ) will be generated based on a proposal distribution  $g$  which depends on the current observation ( $t$ ), i.e.  $g(\cdot | X^{(t)})$
- Since  $(X^{(t+1)})$  depends on  $(X^{(t)})$  but not on earlier observations, the sequence  $(X^{(t)})$  is a Markov chain

# MCMC – Metropolis-Hastings algorithm

- A general method to generate the Markov chain is the Metropolis-Hastings (MH) algorithm

- A starting value  $x^{(0)}$  is generated from some starting distribution

- Given observation  $x^{(t)}$ , generate  $x^{(t+1)}$  as follows:

1. Sample a candidate  $x^*$  from a proposal distribution  $g(\cdot|x^{(t)})$

2. Compute the MH ratio  $R(x^{(t)}, x^*) = \frac{f(x^*) g(x^{(t)}|x^*)}{f(x^{(t)}) g(x^*|x^{(t)})}$

3. Sample  $x^{(t+1)}$  according to

$$x^{(t+1)} = \begin{cases} x^*, & \text{with probability } \min\{R(x^{(t)}, x^*), 1\} \\ x^{(t)}, & \text{otherwise} \end{cases}$$

4. If more observations needed, set  $t \leftarrow t+1$ ; go to 1

## Metropolis algorithm

Special case when

$g$  is symmetric:

$$g(x^*|x^{(t)}) = g(x^{(t)}|x^*)$$

$$= \frac{f(x^*)}{f(x^{(t)})}$$

# Metropolis alg. – Ex.1

- For illustration, we consider two-dimensional distribution with density  $f$  according to contour lines in figure
- Proposal distribution
$$g(x^*|x^{(t)}) = g(x^{(t)}|x^*)$$
$$= \frac{1}{\pi r^2} \mathbf{1}\{\|x^{(t)} - x^*\| < r\}$$
for some constant  $r$  (here=1)

# Metropolis alg. – Ex.1

- Proposal distribution
$$g(x^*|x^{(t)}) = g(x^{(t)}|x^*) = \frac{1}{\pi r^2} \mathbf{1}\{\|x^{(t)} - x^*\| < r\}$$
for some constant  $r$  (here=1)
- Start here with  $x^{(0)} = (1, -0.5)$
- Randomize uniformly on unit circle around  $x^{(0)}$  (proposal distribution); result  $x^* = (0.58, 0.08)$
- $f(x^*) = 0.296 > f(x^{(0)}) = 0.098$ ; so this was an uphill step and is automatically accepted ( $R(x^{(t)}, x^*) = \frac{f(x^*)}{f(x^{(t)})} > 1$ )

# Metropolis alg. – Ex.1

- $x^{(0)} = (1, -0.5)$
- Uphill steps:  $x^{(1)} = (0.58, 0.08)$
- $x^{(2)} = (-0.33, 0.13)$
- $x^{(3)} = (-0.23, 0.05)$
- Then downhill step proposed:  
 $x^* = (-0.32, 0.4)$ ,  
 $R(x^{(t)}, x^*) = \frac{f(x^*)}{f(x^{(t)})} = 0.774$
- Random Unif(0,1) generated: 0.573 and since this is smaller than  $R = 0.774$ ,  $x^{(4)} = x^* = (-0.32, 0.4)$  is accepted
- Again downhill step proposed:  $x^* = (-0.67, 1.31)$ ,  $R(x^{(t)}, x^*) = \frac{f(x^*)}{f(x^{(t)})} = 0.560$ ; random Unif(0,1): 0.890 and rejection of  $x^*$
- $x^{(5)} = x^{(4)} = (-0.32, 0.4)$

# Metropolis alg. – Ex.1

- After several additional iterations (see red lines for rejected proposals), one part of the distribution was explored to a good extend
- Since uphill steps preferred, part of distribution with local maximum at  $(-0.5, -0.5)$  is not yet "detected" at all
- Occasionally, the path will arrive at this part as well

# Metropolis alg. – Ex.1

- Now, larger parts of distribution explored

- A couple of animations can be found on:  
<https://chi-feng.github.io/mcmc-demo/app.html#RandomWalkMH,standard>  
(choose Algorithm: RandomWalkMH)

# Convergence of Metropolis-Hastings

- If Metropolis-Hastings generated sequence  $(X^{(t)})$  is an **irreducible and aperiodic chain** (compare Lecture LM2), the distribution of  $(X^{(t)})$  **converges to target distribution**
- For example, if target distribution is uniform distribution on intervals  $[0, \frac{1}{2}]$  and  $[\frac{3}{2}, 2]$ , and proposal distribution is uniform distribution on  $[X^{(t)} - \frac{1}{2}, X^{(t)} + \frac{1}{2}]$ , the requirements above are violated

# Bayesian analysis

- Data  $y$  is collected and assumed that it is generated according to a distribution with density  $f(y|\theta)$ ;  $\theta$  is a parameter(-vector) to be estimated
- The posterior density is proportional to product of likelihood and prior:

$$f_{\text{posterior}}(\theta|y) = \frac{f(y|\theta) \cdot f_{\text{prior}}(\theta)}{f(y)}, \text{ where } f(y) = \int f(y|\theta) f_{\text{prior}}(\theta) d\theta$$

- We would like to generate the posterior distribution  $f_{\text{posterior}}$
- We have likelihood  $f(y|\theta)$  and an assumption for prior  $f_{\text{prior}}(\theta)$
- For Metropolis-Hastings, we do not need the denominator  $f(y)$ ; it cancels out in the MH ratio (see algorithm):

$$R(x^{(t)}, x^*) = \frac{f_{\text{posterior}}(x^*) g(x^{(t)}|x^*)}{f_{\text{posterior}}(x^{(t)}) g(x^*|x^{(t)})}$$

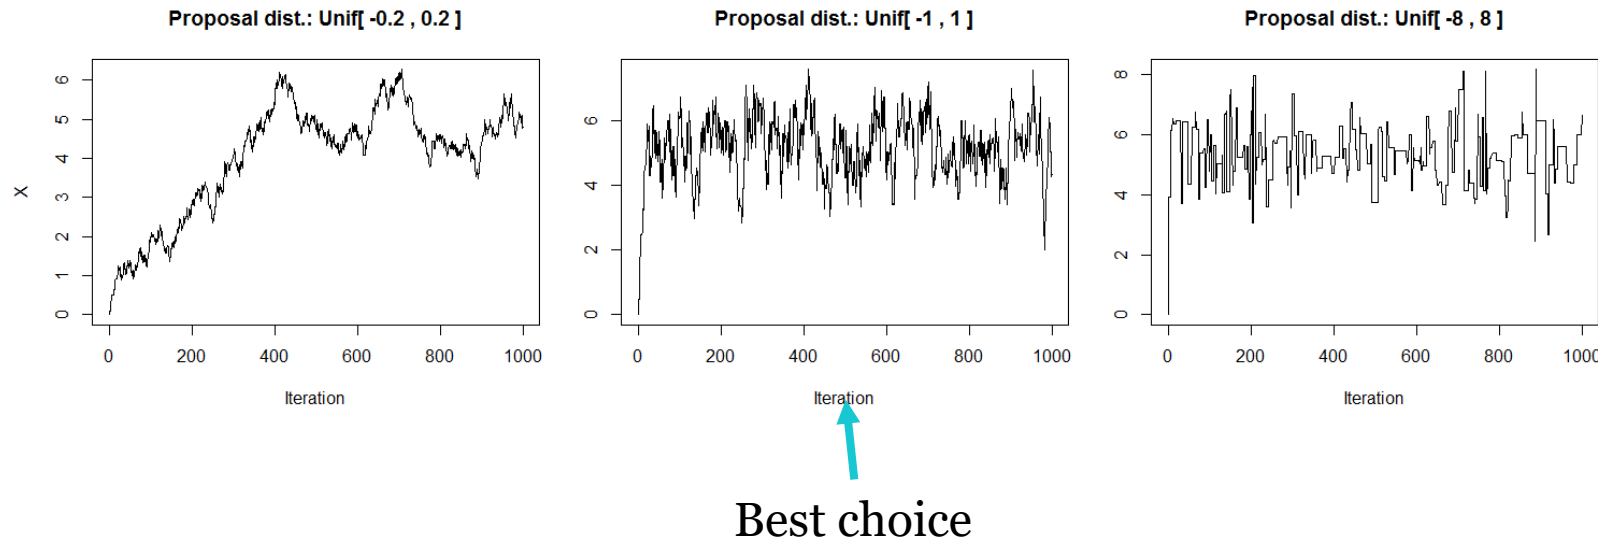

# Metropolis algorithm - Example 2

(compare Givens and Hoeting, ex. 5.3)

- Consider Bayesian estimation of  $\mu$  based on  $N(\mu, 3^2/7)$  likelihood for  $\mu$  and Cauchy(5,2) prior; observed mean=5.38
- The posterior density is proportional to product of likelihood and prior
- **Use MCMC to generate random samples following the posterior density**
- Based on these random samples, one can e.g.
  - determine posterior probability that  $2 \leq \mu \leq 8$
  - determine mean and variance of posterior

# Metropolis algorithm - Example 2

- We use starting value  $x^{(0)} = 0$ ,  $s = 1000$  iterations and following proposal distributions  $g(\cdot | x^{(t)})$ :  
 $x^{(t)} + \text{Unif}[-0.2, 0.2]$ ,  $x^{(t)} + \text{Unif}[-1, 1]$ ,  $x^{(t)} + \text{Unif}[-8, 8]$
- **Sample path plots** show simulated values  $x^{(t)}$  vs. iteration number  $t$

# Metropolis algorithm - Example 2

- Count “acceptance rate” (=proportion accepted proposals)
- Here:                      98%                      78%                      18%
- Best results for 44% (uni-dim. case) to 23.4% (high dim. case) acceptance probability (theory based on normal target and proposal functions, see Givens and Hoeting, Chapter 7.3, for references about that)
- For multimodal functions lower acceptance probabilities might be good

# Metropolis algorithm - Example 2

- Based on sample path plots, we might choose  $x^{(t)} + \text{Unif}[-1,1]$  as proposal distribution
- Often, one wants to discard initial samples (**burn-in** period) which highly depend on starting value, e.g. **50 values +  $x^{(0)}$**

# Metropolis algorithm - Example 2

- For  $s = 10\,000$  iterations and burn-in of 50, we obtain

- Monte Carlo estimate for  $P(2 \leq \mu \leq 8)$  is 0.9967  
(Monte Carlo standard error =  $\sqrt{0.9967 * 0.0033 / 9950} = 0.0006$ )
- Estimated mean = 5.26, standarddeviation = 0.99

# Metropolis algorithm - Example 2

- Were  $s = 10\,000$  iterations enough to ensure convergence?
- Can depend on the purpose ...
- E.g. for estimating  $P(2 \leq \mu \leq 8)$
- One can monitor cusum/convergence plots showing estimate versus iterations (see Givens and Hoeting, ch.7.3.1.1)
- After 10 000 iterations

After 100 000 iterations

- After 10 000 iterations, we might not be happy with the left graph; we run longer and are happy with 100 000

# Metropolis-Hastings with independent proposals

- Other proposal distributions  $g$  possible (not necessarily symmetric), e.g. independent proposals
- Proposal distribution depends not on previous value,  $g(\cdot | x^{(t)}) = g(\cdot)$
- The MH ratio is 
$$R(x^{(t)}, x^*) = \frac{f(x^*) g(x^{(t)} | x^*)}{f(x^{(t)}) g(x^* | x^{(t)})} = \frac{f(x^*)/g(x^*)}{f(x^{(t)})/g(x^{(t)})}$$
- A possible application is for Bayesian analysis ( $f$  is the posterior) with proposal distribution  $g$  being the prior distribution
- $f/g$  is then the likelihood

# Gibbs sampling

- Situation:
  - We want to sample a multivariate distribution  $f(x_1, \dots, x_d)$  and this density is difficult to sample from
  - The conditional distributions for each single dimension  $i$  given fixed values  $x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_d$  are easy to sample from
- Gibbs sampling generates a Markov chain converging to distribution  $f$  in this situation
- We sample one dimension in turn

# Gibbs sampling

- The algorithm:

- o. A starting value  $\mathbf{x}^{(0)} = (x_1^{(0)}, x_2^{(0)}, \dots, x_d^{(0)})$  is chosen

- 1. Generate  $x_1^{(t+1)}$  following  $f(x_1 | x_2^{(t)}, \dots, x_d^{(t)})$

- 2. Generate  $x_2^{(t+1)}$  following  $f(x_2 | x_1^{(t+1)}, x_3^{(t)}, \dots, x_d^{(t)})$

- ...

- i. Generate  $x_i^{(t+1)}$  following  $f(x_i | x_1^{(t+1)}, \dots, x_{i-1}^{(t+1)}, x_{i+1}^{(t)}, \dots, x_d^{(t)})$

- ...

- d. Generate  $x_d^{(t+1)}$  following  $f(x_d | x_1^{(t+1)}, \dots, x_{d-1}^{(t+1)})$

- Go back to 1. if more points needed

# Gibbs sampling – Example 3

- Let  $f(x_1, x_2) = c \cdot \mathbf{1}\{x_1^2 + 1.8 \cdot x_1 x_2 + x_2^2 < 1\}$  be the uniform distribution on the ellipse 
$$x_1^2 + 1.8 \cdot x_1 x_2 + x_2^2 < 1$$
  - The conditional distribution for  $x_2$  given  $x_1$  is a uniform distribution on the interval  $(-0.9x_1 - \sqrt{1 - 0.19x_1^2}, -0.9x_1 + \sqrt{1 - 0.19x_1^2})$  if the term below the root is positive
- You can obtain these boundaries by solving  $x_1^2 + 1.8 \cdot x_1 x_2 + x_2^2 - 1 = 0$  for  $x_2$
- $x_1$  given  $x_2$  has a similar distribution with  $x_2$  instead of  $x_1$  in the boundaries
